

APPARATUS AND METHOD FOR PACING MODE SWITCHING DURING ATRIAL TACHYARRHYTHMIAS

Field of the Invention

5 This invention pertains to cardiac pacemakers and methods for operating such devices. In particular, the invention relates to methods for cardiac pacing during an atrial tachyarrhythmia.

Cross Reference To Related Applications

10 This application is related to the following co-pending, commonly assigned patent application: "System Providing Ventricular Pacing and Biventricular Coordination," serial number 09/316,588 (Attorney Docket No. 00279.160US1), which disclosure is herein incorporated by reference in its entirety.

Background

15 Congestive heart failure (CHF) is a clinical syndrome in which an abnormality of cardiac function causes cardiac output to fall below a level adequate to meet the metabolic demand of peripheral tissues. CHF can be due to a variety of etiologies with that due to ischemic heart disease being the most common. Some form of cardiac pacing
20 can often benefit CHF patients. For example, sinus node dysfunction resulting in bradycardia can contribute to heart failure which can be corrected with conventional bradycardia pacing. Also, some CHF patients suffer from some degree of AV block such that their cardiac output is improved by synchronizing atrial and ventricular contractions with dual-chamber pacing using a programmed AV delay time (i.e., atrial triggered
25 ventricular pacing or AV sequential pacing).

 A common sequela of CHF is dilation of the heart chambers (especially the left ventricle) as end-diastolic volume is increased in the body's attempt to increase stroke volume. The ventricles can then become stretched and less contractile which actually worsens the heart failure. Stretching of the ventricular wall can also cause slowed
30 conduction of depolarization impulses through the ventricle. If conduction velocity is slowed in the left ventricle more than the right, for example, the contraction of the two ventricles during ventricular systole becomes uncoordinated which lessens pumping

efficiency. Some CHF patients also suffer from conduction defects of the specialized conduction system of the heart (a.k.a. bundle branch blocks) so that a depolarization impulse from the AV node reaches one ventricle before the other. In both of these situations, cardiac output can be increased by improving the synchronization of right and left ventricular contractions. Cardiac pacemakers have therefore been developed which provide pacing to both ventricles. (See, e.g., U.S. Patent Number 4,928,688, issued to Mower and hereby incorporated by reference.)

Due to stretching of the atrial walls caused by the cardiac dilation described above, CHF patients are predisposed to occurrence of atrial tachyarrhythmias. Atrial tachyarrhythmias are cardiac rhythms characterized by atrial contractions occurring at a rapid rate, either due to an ectopic excitatory focus or abnormal excitation by normal pacemaker tissue. Atrial tachyarrhythmias can be classified according to increasing rate into entities that include atrial tachycardia, atrial flutter, and atrial fibrillation. Due to the refractory period of the AV node, some degree of AV block is usually always present so that the ventricular rate is less than the atrial rate if the AV conduction pathway is otherwise intact. In atrial fibrillation, the atria depolarize in a chaotic fashion with no effective pumping action, and the ventricles beat both rapidly and irregularly due to conduction of excitatory impulses from the fibrillating atria through the AV node. In atrial tachyarrhythmias, and especially atrial fibrillation, the atria no longer act as effective primer pumps for the ventricles which decreases stroke volume, referred to as a loss of atrio-ventricular synchrony. Also, when the ventricles contract at irregular intervals, the contraction can occur prematurely before diastolic filling is complete and decrease the stroke volume for that contraction. An episode of atrial tachyarrhythmia can thus depress cardiac output and cause such symptoms as dyspnea, fatigue, vertigo, and angina. This is especially problematic in CHF patients who are already hemodynamically compromised.

Summary of the Invention

The present invention relates to a method and system for altering the pacing mode of a pacemaker in order to maintain hemodynamic stability during an atrial tachyarrhythmia such as atrial fibrillation. The invention may be especially beneficial to

pacemaker patients with CHF whose hemodynamics are adversely affected by episodes of atrial fibrillation.

In accordance with the invention, the pacing mode of a pacemaker is switched from a normal pacing mode to an atrial fibrillation pacing mode in response to detection of an atrial tachyarrhythmia. The atrial fibrillation pacing mode is adapted for pacing in the presence of an irregular intrinsic ventricular rhythm. Depending upon the individual patient and the normal pacing mode, the atrial fibrillation mode may include initiation or modification of ventricular resynchronization therapy, initiation of ventricular rate regularization pacing, and/or changes to rate-adaptive parameters.

In one embodiment, the atrial fibrillation mode includes ventricular resynchronization, wherein pacing stimulation is applied to both ventricles or to one ventricle in a manner that improves the coordination of ventricular contractions. Such pacing is beneficial in patients with interventricular or intraventricular conduction defects, and switching to a resynchronization mode during an episode of atrial tachyarrhythmia improves cardiac output in those patients. If the normal pacing mode already includes resynchronization therapy, it may be beneficial to modify the resynchronization in the atrial fibrillation mode by, for example, adjusting a biventricular offset value or initiating biventricular triggered pacing.

In another embodiment, the atrial fibrillation mode includes ventricular rate regularization where a ventricular escape interval is dynamically adjusted in accordance with a measured intrinsic ventricular rate. By adjusting the ventricular escape interval to more nearly match the intrinsic ventricular rate, more paces are delivered and less variability in the overall ventricular rhythm is allowed. With a more regular ventricular rate, cardiac output is improved during an atrial tachyarrhythmia. Ventricular rate regularization may also enhance the effectiveness of ventricular resynchronization pacing in the presence of an atrial tachyarrhythmia by increasing the number of paces delivered.

Brief Description of the Drawings

Fig. 2 shows an exemplary filter implementation of a ventricular rate regularization system.

Fig. 3 is a block diagram illustrating exemplary atrial fibrillation pacing modes.

Description of the Invention

The most common condition for which pacemakers are used is in the treatment of
 5 bradycardia, where the ventricular rate is too slow. Atrio-ventricular conduction defects
 (i.e., AV block) that are fixed or intermittent and sick sinus syndrome represent the most
 common causes of bradycardia for which permanent pacing may be indicated. If
 functioning properly, a pacemaker makes up for the heart's inability to pace itself at an
 appropriate rhythm in order to meet metabolic demand by enforcing a minimum heart
 10 rate. As described below, bradycardia pacing modes define which chambers are paced
 and the manner in which the paces are delivered. Pacing therapy can also be used in the
 treatment of congestive heart failure (CHF). Some CHF patients suffer from some degree
 of AV block or are chronotropically deficient such that their cardiac output can be
 improved with conventional bradycardia pacing. It has also been shown, however, that
 15 some CHF patients suffer from intraventricular and/or interventricular conduction defects
 such that their cardiac outputs can be increased by improving the synchronization of right
 and left ventricular contractions with electrical stimulation, referred to herein as
 ventricular resynchronization therapy.

A pacemaker patient with some degree of CHF who experiences an episode of
 20 atrial fibrillation will suffer some diminishing of cardiac output from the resulting
 irregular ventricular rhythm and/or loss of atrio-ventricular synchrony. Thus, even if a
 patient were adequately treated during normal circumstances with only a bradycardia
 pacing mode, the same patient may benefit from resynchronization therapy to restore
 hemodynamic stability during the atrial fibrillation episode. Furthermore, patients treated
 25 with resynchronization therapy in addition to a bradycardia pacing mode may benefit
 from a modification to the pacing mode including changes to the mode of
 resynchronization. The present invention relates to a method for operating a pacemaker
 in which a normal pacing mode is switched to an atrial fibrillation pacing mode upon
 detection of an atrial tachyarrhythmia such as atrial fibrillation that counteracts the
 30 adverse effects of atrial fibrillation.

1. Hardware Platform

Cardiac pacemakers are cardiac rhythm management devices that provide electrical stimulation in the form of pacing pulses to selected chambers of the heart. (As the term is used herein, a pacemaker is any cardiac rhythm management device that performs cardiac pacing, including implantable cardioverter/defibrillators having a pacing functionality.) Cardiac rhythm management devices are typically implanted subcutaneously in a patient's chest and have leads threaded intravenously into the heart to connect the device to electrodes used for sensing and pacing, the electrodes being disposed in proximity to selected chambers of the heart. Pacemakers typically have a programmable electronic controller that causes the pacing pulses to be output in response to lapsed time intervals and sensed electrical activity (i.e., intrinsic heart beats not as a result of a pacing pulse). A depolarization wave associated with an intrinsic contraction of the atria or ventricles that is detected by the pacemaker is referred to as an atrial sense (P wave) or ventricular sense (R wave), respectively. In order to cause such a contraction in the absence of an intrinsic beat, a pacing pulse with energy above a certain pacing threshold is delivered to the chamber.

Fig. 1 shows a system diagram of a microprocessor-based pacemaker physically configured with sensing and pacing channels for the atrium and both ventricles. The controller 10 of the pacemaker is a microprocessor which communicates with a memory 12 via a bidirectional data bus. The memory 12 typically comprises a ROM (read-only memory) for program storage and a RAM (random-access memory) for data storage. The pacemaker has atrial sensing and pacing channels comprising electrode 34, lead 33, sensing amplifier 31, pulse generator 32, and an atrial channel interface 30 which communicates bidirectionally with a port of microprocessor 10. The device also has ventricular sensing and pacing channels for both ventricles comprising electrodes 24a-b, leads 23a-b, sensing amplifiers 21a-b, pulse generators 22a-b, and ventricular channel interfaces 20a-b where "a" designates one ventricular channel and "b" designates the other. For each channel, the same lead and electrode are used for both sensing and pacing. The channel interfaces 20a-b and 30 include analog-to-digital converters for digitizing sensing signal inputs from the sensing amplifiers and registers which can be written to by the microprocessor in order to output pacing pulses, change the pacing pulse

amplitude, and adjust the gain and threshold values for the sensing amplifiers. An exertion level sensor 330 (e.g., an accelerometer or a minute ventilation sensor) enables the controller to adapt the pacing rate in accordance with changes in the patient's physical activity. A telemetry interface 40 is also provided for communicating with an external programmer. A pacemaker incorporating the present invention may possess all of the components in Fig. 1 and be programmable so as to operate in a number of different modes, or it may have only those components necessary to operate in a particular mode.

The controller 10 controls the overall operation of the device in accordance with programmed instructions stored in memory. The controller 10 controls the delivery of paces via the pacing channels in accordance with a pacing mode, interprets sense signals from the sensing channels, and implements timers for defining escape intervals and sensory refractory periods. The controller also detects the presence of arrhythmias such as atrial fibrillation by measuring the time interval between senses and implements the mode switching function as described herein. It should be appreciated that these functions could also be performed by custom logic circuitry either in addition to or instead of a programmed microprocessor.

2. Bradycardia Pacing Modes

Bradycardia pacing modes are generally designated by a letter code of three positions where each letter in the code refers to a specific function of the pacemaker. The first letter refers to which heart chambers are paced and which may be an A (for atrium), a V (for ventricle), D (for both chambers), or O (for none). The second letter refers to which chambers are sensed by the pacemaker's sensing channels and uses the same letter designations as used for pacing. The third letter refers to the pacemaker's response to a sensed P wave from the atrium or an R wave from the ventricle and may be an I (for inhibited), T (for triggered), D (for dual in which both triggering and inhibition are used), and O (for no response). Modern pacemakers are typically programmable so that they can operate in any mode which the physical configuration of the device will allow. Additional sensing of physiological data allows some pacemakers to change the rate at which they pace the heart in accordance with some parameter correlated to metabolic

demand. Such pacemakers are called rate-adaptive pacemakers and are designated by a fourth letter added to the three-letter code, R.

Pacemakers can enforce a minimum heart rate either asynchronously or synchronously. In asynchronous pacing, the heart is paced at a fixed rate irrespective of intrinsic cardiac activity. There is thus a risk with asynchronous pacing that a pacing pulse will be delivered coincident with an intrinsic beat. Most pacemakers for treating bradycardia today are therefore programmed to operate synchronously in a so-called demand mode where sensed cardiac events occurring within a defined interval either trigger or inhibit a pacing pulse. Inhibited demand pacing modes utilize escape intervals to control pacing in accordance with sensed intrinsic activity. In an inhibited demand mode, a pacing pulse is delivered to a heart chamber during a cardiac cycle only after expiration of a defined escape interval during which no intrinsic beat by the chamber is detected. If an intrinsic beat occurs during this interval, the heart is thus allowed to "escape" from pacing by the pacemaker. Such an escape interval can be defined for each paced chamber. For example, a ventricular escape interval can be defined between ventricular events so as to be restarted with each ventricular sense or pace. The inverse of this escape interval is the minimum rate at which the pacemaker will allow the ventricles to beat, sometimes referred to as the lower rate limit (LRL).

In atrial tracking pacemakers (i.e., VDD or DDD mode), another ventricular escape interval is defined between atrial and ventricular events, referred to as the atrio-ventricular interval (AVI). The atrio-ventricular interval is triggered by an atrial sense or pace and stopped by a ventricular sense or pace. A ventricular pace is delivered upon expiration of the atrio-ventricular interval if no ventricular sense occurs before. Atrial-triggered ventricular pacing attempts to maintain the atrio-ventricular synchrony occurring with physiological beats whereby atrial contractions augment diastolic filling of the ventricles. If a patient has a physiologically normal atrial rhythm, atrial-triggered pacing also allows the ventricular pacing rate to be responsive to the metabolic needs of the body. Atrial tracking modes are contraindicated when there is chronic refractory atrial tachyarrhythmia such as atrial fibrillation or atrial flutter.

A pacemaker can also be configured to pace the atria on an inhibited demand basis. An atrial escape interval is then defined as the maximum time interval in which an

atrial sense must be detected after a ventricular sense or pace before an atrial pace will be delivered. When atrial inhibited demand pacing is combined with atrial-triggered ventricular demand pacing (i.e., DDD mode), the lower rate interval is then the sum of the atrial escape interval and the atrio-ventricular interval.

5 Rate-adaptive pacemakers modulate the ventricular and/or atrial escape intervals base upon measurements corresponding to physical activity. Such pacemakers are applicable to situations in which atrial tracking modes cannot be use. In a rate-adaptive pacemaker operating in a ventricular pacing mode, the LRL is adjusted in accordance with exertion level measurements such as from an accelerometer or minute ventilation
10 sensor in order for the heart rate to more nearly match metabolic demand. The adjusted LRL is then termed the sensor-indicated rate.

3. Ventricular Resynchronization Therapy

15 In a ventricular resynchronization pacing mode, pacing stimulation is applied to one or both ventricles in a manner that improves the coordination of ventricular contractions and thereby improves ventricular pumping efficiency. In delivering such therapy, for example, it may be useful to pace only one ventricle on an inhibited demand basis in accordance with sense signals received from the opposite ventricle, pace one ventricle in a triggered mode in which an intrinsic beat in one ventricle triggers a pace in
20 the opposite ventricle, pace both ventricles on an inhibited demand basis in accordance with sense signals received from only one ventricle, or pace both ventricles in a combination of triggered and inhibited demand modes. In the examples of resynchronization therapy that follow, the ventricular pacing modes are based upon intrinsic activity in the right ventricle. It should be appreciated, however, that equivalent
25 embodiments could be applied to pacing modes based upon left ventricular intrinsic activity.

One implementation of resynchronization therapy is biventricular (BV) pacing. In BV pacing, a left ventricular pace is delivered either simultaneously or in a timed relation with a right ventricle pace as specified by a biventricular offset interval. The offset
30 interval may be zero in order to pace both ventricles simultaneously, positive in order to pace the left ventricle after the right, or negative if the left ventricle is paced before the

right. In many cases, pumping efficiency of the heart will be increased by simultaneous pacing of the ventricles with an offset of zero. However, it may be desirable in certain patients to pace one ventricle before the other in order to compensate for different conduction velocities in the two ventricles, and this may be accomplished by specifying a particular biventricular offset interval. The ventricles may be paced on an inhibited demand basis where the ventricular escape interval is restarted with either a ventricular pace or a right ventricular sense. The pacing mode may also include atrial tracking. In that case, a pair of ventricular paces are delivered after expiration of the AVI escape interval or expiration of the LRL escape interval, with ventricular pacing inhibited by a right ventricular sense that restarts the LRL escape interval or stops the AVI escape interval. Since the ventricular escape interval in this mode is reset or stopped by senses only from the right ventricle, a left ventricular protection period may be provided that starts with the occurrence of a left ventricular sense and lasts for a specified time. A left ventricular pace is then not permitted upon expiration of the escape interval if it would occur within the protection period.

A variation of biventricular pacing is to pace only the left ventricle (LV-only pacing). LV-only pacing may be advantageous where the conduction velocities within the ventricles are such that pacing only the left ventricle results in a more coordinated contraction by the ventricles than with conventional right ventricular pacing or biventricular pacing. LV-only pacing may be implemented in inhibited demand modes with or without atrial tracking, similar to biventricular pacing. A left ventricular pace is then delivered upon expiration of the AVI escape interval or expiration of the LRL escape interval, with left ventricular pacing inhibited by a right ventricular sense that restarts the LRL escape interval or stops the AVI escape interval. As with BV pacing, a left ventricular pace may be inhibited if a left ventricular sense occurs within a protective period prior to expiration of the ventricular escape interval. Since an inhibited left ventricular pace in this mode could result in a cardiac cycle with no pacing, the mode may be further modified such that a right ventricular safety pace is delivered if the left ventricular pace is inhibited and no right ventricular sense has occurred.

Another ventricular resynchronization mode is a biventricular triggered (BT) mode where one or both ventricles are paced within a latency period following a sense

from the right ventricle. In this mode, rather than inhibiting pacing upon receipt of a right ventricular sense, ventricular pacing is triggered to occur in the shortest time possible after a right ventricular sense in order produce a coordinated contraction of the ventricles. This mode of pacing may be desirable when the intraventricular conduction time of the heart is long enough that the pacemaker is able to reliably insert a pace before depolarization from the right ventricle would reach the left ventricle. The time delay between a right ventricular sense and the ensuing pace output is dictated by the response time of the hardware and is designated as the sense-to-pace latency (SPL) interval. Note that the SPL interval is a characteristic of the hardware and not a programmable timer interval. The mode may operate such that following a right ventricular sense, either the left ventricle only is paced, or both ventricles are paced. In the latter case, the right ventricle is paced even though a right ventricular sense has been received to allow for the possibility that the right ventricular sense was actually a far-field left ventricular sense in the right ventricular channel. If the right ventricular sense were actually from the right ventricle, the right ventricular pace would occur during the right ventricle's physiological refractory period and be of no consequence. With either type of BT pacing mode, pacing of the left ventricle can be inhibited by a left ventricular sense that triggers a left ventricular protective period interval. Biventricular triggered pacing can also be combined with biventricular inhibited demand pacing.

4. Ventricular Rate Regularization

Ventricular rate regularization (VRR) is a ventricular pacing mode in which the LRL of the pacemaker is dynamically adjusted in accordance with a detected intrinsic ventricular rate. When a pacemaker is operating in a ventricular pacing mode (e.g., VVI), intrinsic ventricular beats occur when the instantaneous intrinsic rate rises above the LRL of the pacemaker. Otherwise, paces are delivered at a rate equal to the LRL. Thus, paces are interspersed with intrinsic beats, and the overall ventricular rhythm as a result of both paces and intrinsic beats is determined by the LRL and the mean value and variability of the intrinsic ventricular rate. VRR regularizes the overall ventricular rhythm by adjusting the LRL of the pacemaker in accordance with changes in the measured intrinsic rate.

The intrinsic ventricular rate is the rate at which intrinsic ventricular beats occur

and can be defined both instantaneously and as being at some mean value with a certain variability about that mean. The instantaneous intrinsic rate can be determined by measuring an R-R interval, where an R-R interval is the time between a present ventricular sense (i.e., an R-wave or intrinsic ventricular depolarization) and the preceding ventricular sense or ventricular pace, with the instantaneous rate being the reciprocal of the measured interval. The LRL of a pacemaker is initially set to a programmed base value and defines the ventricular escape interval, which is the maximum time between ventricular beats allowed by the pacemaker and is the reciprocal of the LRL. At any particular mean intrinsic rate above the LRL, a ventricular pace is delivered only when, due to the variability in the intrinsic rate, an R-R interval would be longer than the ventricular escape interval were it allowed to occur. As the mean intrinsic ventricular rate increases above the LRL, fewer paces are delivered and more variability in the overall ventricular rhythm is allowed. The VRR pacing mode counteracts this by increasing the LRL as the intrinsic ventricular rate increases to thereby increase the frequency of paced beats and lessen the variability in the overall ventricular rate. The VRR mode then decreases the LRL toward its base value as the number of paces delivered increases due to a decrease in either the mean intrinsic ventricular rate or its variability. The LRL adjusted in this manner is also referred to herein as the VRR-indicated rate.

In one embodiment of VRR, the LRL is adjusted by measuring an R-R interval when a ventricular sense occurs and then computing an updated ventricular escape interval based upon the measured R-R interval. When a ventricular pace is delivered, on the other hand, the LRL is made to decay toward the programmed base value. Fig. 2 shows an exemplary implementation of a VRR system made up of a pair of filters 515 and 516 which may be implemented as software executed by the controller 10 and/or with discrete components. Filter 515 is employed to compute the updated ventricular escape interval when a ventricular sense occurs, and filter 516 is used when a ventricular pace is delivered.

When a ventricular sense occurs, the measured R-R interval is input to a recursive digital filter 515 whose output is the updated ventricular escape interval. The filter 515 multiplies the measured R-R interval by a filter coefficient A and then adds the result to

the previous value of the output (i.e., the present ventricular escape interval) multiplied by a filter coefficient B . The operation of the filter is thus described by $VEI_n = A(RR_n) + B(VEI_{n-1})$, where A and B are selected coefficients, RR_n is the most recent R-R interval duration, and VEI_{n-1} is the previous value of the ventricular escape interval. A useful way to conceptualize the filter 515 is to decompose the coefficients A and B into a scaling factor a and a weighting coefficient w such that $A = a \cdot w$ and $B = (1-w)$, where w is between 0 and 1. Viewed this way, the filter is seen as computing a weighted average of the present R-R interval multiplied by the scaling factor a and the present ventricular escape interval. The filter thus causes the value of the ventricular escape interval to move toward the present R-R interval multiplied by the scaling factor at a rate determined by the weighting coefficient. This corresponds to the filter moving the pacemaker's LRL toward a fraction $1/a$ of the instantaneous intrinsic ventricular rate as determined by the measured R-R interval. If a ventricular sense has occurred, the current LRL is necessarily less than the measured instantaneous intrinsic ventricular rate. If it is also less than $1/a$ of the intrinsic rate, the LRL is increased by the filter up to a value that is $1/a$ of the intrinsic rate to result in more pacing and less variability in the overall ventricular rhythm.

When a ventricular pace is delivered due to expiration of the ventricular escape interval without a ventricular sense, filter 516 multiplies the present ventricular escape interval by a filter coefficient C so that $VEI_n = C(VEI_{n-1})$. To provide stable operation, the coefficient C must be set to a value greater than 1. Filter 516 then causes the ventricular escape interval to increase in an exponential manner with each pace as successive values of the escape interval are input to the filter up to a value corresponding to the base LRL.

The updating of the ventricular escape interval may be performed in various ways including on a beat-to-beat basis, at periodic intervals, or with averages of successive R-R intervals. In a presently preferred embodiment, however, the updating is performed on a beat-to-beat basis with each ventricular sense or pace causing adjustment of the LRL by filter 515 or 516, respectively. The two filters operating together thus cause the LRL to move closer to $1/a$ of the measured intrinsic rate after a ventricular sense and to decay toward the base LRL value after a ventricular pace.

The coefficients a and w (or A and B) and C are selected by the user and may be made programmable so that the behavior of the system can be adjusted to produce the

clinically best result in an individual patient. For example, as the scaling factor a is made greater than 1, the filter 515 causes the LRL to move toward a smaller fraction $1/a$ of the detected intrinsic rate which allows more intrinsic beats to occur and greater variability in the overall rhythm. As a is decreased back toward 1, the filter 515 tends to move the

5 LRL of the pacemaker toward a larger fraction of the detected instantaneous intrinsic rate, thus increasing the amount of pacing and decreasing the amount of variability allowed in the overall ventricular rhythm. If a is made smaller than 1, the LRL is moved toward a rate higher than the intrinsic rate, further increasing the amount of pacing to point where most of the ventricular rhythm is made up of paced beats. The larger the weighting factor

10 w , the faster the LRL is moved to the specified fraction of the intrinsic rate, making the system more responsive to increases in the variability of the intrinsic rhythm. The larger the decay coefficient C , the more rapidly will filter 516 cause the LRL to decrease toward its programmed base value when ventricular paces are delivered due to no ventricular senses being detected within the ventricular escape interval. The controller limits the

15 updated ventricular escape interval as a result of the operations of filters 515 and 516 to minimum and maximum values in accordance with a programmed maximum pacing rate MPR and base lower rate limit LRL, respectively.

As noted, the coefficients of filters 515 and 516 can be made programmable by the user, such as by using a remote programmer. In another embodiment, the user selects

20 a desired performance parameter (e.g., desired degree of rate regularization, desired amount of pacing, desired decay rate, etc.) from a corresponding range of possible values. The appropriate combinations of coefficients for filters 515 and 516 are then automatically selected to provide filter settings that correspond to the selected user-programmed performance parameter. The filter coefficients can also be made functions

25 of other parameters, such as the measured R-R interval and current LRL setting, and dynamically adjusted.

The VRR system in this embodiment uses the programmed base LRL of the pacemaker as the lower limit to which the LRL is permitted to decay when no ventricular senses are detected. The base LRL can be changed periodically by the user with an

30 external programmer, and rate-adaptive pacemakers have the capability of dynamically adjusting the LRL in order to adapt to exercise. If a rate-adaptive pacemaker is operated

in a VRR mode, the sensor-indicated rate can simply be regarded by the pacemaker as the base LRL. The lower limit for the VRR-indicated rate is then the sensor-indicated rate rather than the programmed base LRL.

5. Pacing Mode Switching During Atrial Fibrillation

Fig. 3 is a block diagram illustrating examples of an atrial fibrillation pacing mode that is switched to upon detection of an atrial tachyarrhythmia. An atrial tachyarrhythmia, such as atrial fibrillation, is detected at block 300 while the pacemaker is operating in its normal mode. Atrial triggered ventricular pacing is contraindicated during an atrial tachyarrhythmia because atrial rate tracking would result in ventricular pacing that is too rapid. If the normal mode incorporates atrial tracking and/or atrial pacing, therefore, the atrial fibrillation mode includes a reversion to a non-atrial triggered ventricular pacing mode (i.e., VVx mode) as shown at block 301. The atrial fibrillation mode may also include one or more other pacing modes, each of which will be discussed in turn.

The atrial fibrillation mode may include initiation of ventricular rate regularization as shown at block 302. If AV conduction is intact in a patient, atrial fibrillation results in a very rapid and intrinsic ventricular rhythm, and regularizing the ventricular rate improves cardiac output directly through its effect on diastolic filling. Ventricular rate regularization may be applied in this instance with parameter settings such that the ventricles are driven at a rate near the intrinsic rate. The intrinsic ventricular rhythm that occurs during an episode of atrial fibrillation is a result of the chaotically occurring depolarizations occurring in the atria being passed through the AV node to the ventricles. The intrinsic ventricular rate is thus governed by the cycle length of the atrial fibrillation and the refractory period of the AV node. If a ventricular pacing pulse is delivered before the next intrinsic beat occurs, the ventricular depolarization is conducted retrogradely to the AV node causing late depolarization of the AV node during the ventricular beat. The refractory period of the AV node is also delayed, which delays the time before an atrial depolarization can be conducted through the node to result in an intrinsic beat. The effect of the pace is thus to lengthen the time until the next intrinsic beat. Ventricular rate regularization at a pacing rate near the intrinsic ventricular rate is

thus especially effective at regularizing the ventricular rate during atrial fibrillation.

Ventricular resynchronization therapy may also be initiated as part of the atrial fibrillation mode. In pacemaker patients having some degree of interventricular or intraventricular conduction delays, a ventricular resynchronization pacing mode can
 5 improve cardiac output by improving the coordination of ventricular contractions. Although cardiac output may be adequate in some of these patients during normal circumstances even without ventricular resynchronization pacing, an episode of atrial fibrillation with loss of atrio-ventricular synchrony and irregular diastolic filling may cause the conduction deficits to become clinically evident. Switching the pacemaker to a
 10 ventricular resynchronization pacing mode may then be helpful in maintaining cardiac output when atrial fibrillation is detected.

Resynchronization pacing as incorporated into the atrial fibrillation mode may be delivered in a number of different pacing modes. One such resynchronization pacing mode is biventricular pacing with or without an offset interval. This mode can be
 15 combined with the reverted to VVI bradycardia pacing mode to result in biventricular pacing on an inhibited demand basis as depicted at block 304. Other alternatives for the atrial fibrillation mode are biventricular-triggered and LV-only pacing modes as shown by blocks 306 and 303, respectively. Biventricular-triggered resynchronization pacing may be particularly useful when the intrinsic ventricular rate is irregular as it allows
 20 reliable delivery of resynchronization pulses based upon the irregular rate. It may also be advantageous to combine resynchronization pacing with ventricular rate regulation as the ventricular rate regulation can be set to increase the amount of pacing and, therefore, the amount of resynchronization. If ventricular resynchronization is part of the normal pacing mode, the atrial fibrillation mode may then include particular modification of
 25 resynchronization pacing parameters such as adjustments to the biventricular offset interval designated by block 305, or switching to an alternative resynchronization pacing mode or switching to additional or alternate pacing sites.

The diminished cardiac output that occurs during atrial fibrillation can also be partially counteracted by making the pacing rate responsive to measured exertion levels.
 30 Accordingly, the atrial fibrillation mode may also include switching from non-rate adaptive to rate-adaptive pacing as shown at block 308, and/or modification of rate-

adaptive parameters as shown at block 307. In the latter case, for example, the rate-response curve that maps a given exertion level to a particular pacing rate may be adjusted to make the pacemaker more responsive, and/or the base lower rate limit corresponding to a resting exertion level could be increased.

5 Although the invention has been described in conjunction with the foregoing specific embodiment, many alternatives, variations, and modifications will be apparent to those of ordinary skill in the art. Such alternatives, variations, and modifications are intended to fall within the scope of the following appended claims.
